

## Watershed Analysis Re: Water Yield Increases

### Introduction

The need to assess the potential of forest harvesting to increase water flows is identified as an indicator and goal in the recent draft of “Alberta Forest Management Planning Standard” released by Alberta Sustainable Resource Development (ASRD 2005) for public comment. The protection of water and water related resources are identified as a “performance standard” with the objective of limiting the impact of timber harvesting on water yield and water quality. The document states that,

“The impacts on water yield must be predicted. Watershed modeling and analysis will determine an acceptable target for water yield increase following harvesting for third order watercourses. The ToR (*Terms of Reference*) will describe the models to be used and assessments to be completed.”

Many forest companies are already addressing these issues in their Detailed Forest Management Plans, even though specific models, methods and targets are not fully established. To date such issues are reconciled between forest companies and ASRD on a one-to-one basis.

### Objectives

The objective of this document is to describe and provide a scientific basis for the protocol developed by Weyerhaeuser Canada Ltd to identify and analyze watersheds to limit any “negative” effects of forest harvesting on water and water related resources.

### Watershed Analysis Protocol

The protocol consists of five steps.

**Step 1.** All fourth order watersheds in the FMA will be screened to determine if the combined percentage of coniferous stands < 35 years old and deciduous stands < 20 years old equals or exceeds 40% of total watershed area.

**Step 2** If the combined percentage for coniferous and deciduous species exceeds 40%, the ECA-AB model (Silins 2003) which simulates increases in annual water yield and hydrologic recovery as a function of the growth of forest regeneration.

**Step 3** If simulated increases in annual water yield exceed 20%, the harvest plan will be modified, or further analyses will be conducted.

**Step 4** Further analyses would use the Wrenss model (Water Resource Evaluation of Non-Point Silvicultural Sources), which provides a more in depth analysis of potential increases in water yield and peak flows.

**Step 5** If a Wrenss analysis still indicates increases in annual water yield are > 20%, harvest plans will be modified.

## Justification for Protocol

The protocol proposes an ECA analysis will only be done for a watershed when 40% of its area contains coniferous and deciduous stands less than 35 years and 20 years in age respectively. Step 1 assumes that significant increases in annual water yield occur when more than 40% of a 3<sup>rd</sup> - 4<sup>th</sup> order watershed is cut, and that hydrologic recovery occurs for coniferous and deciduous stands at 35 and 20 years respectively.

The harvest limit of 40% is supported by the following information.

1. The potential to increase annual water yield is proportional to the area harvested in a watershed is well documented in the scientific literature (Bosch and Hewlett 1982). Reported increases in annual water yield vary from 0%-66%, with maximums occurring in climatic zones characterized by high annual precipitation and warm temperatures. Water yield increases documented in Canada are lower (Hetherington 1987), because of cooler temperatures and less precipitation. Increases in water yield usually occur within the first 1-2 years following harvesting, and then steadily decline with the regrowth of forest cover (i.e. hydrologic recovery).
2. A literature review of experimental watershed studies in a paper by Guillemette *et al* (2005) report that harvesting between 40%-50% of a watershed is sufficient to increase 2-year peak flows by 50%, which may result in changes in stream channel morphology and aquatic habitat. The authors in their conclusions stated that more research is needed to confirm the link between increased peak flows and changes in aquatic habitat.
3. Verry (2004) in a retrospective study of the effects of forest cover removal for agricultural development in the Midwestern U. S. also cites increases in the 2-year event as a factor causing changes in stream channel morphology and aquatic habitats. Such changes in stream channel morphology are usually gradual in nature possibly taking 60-100 years to become apparent.

The use of stand ages of 35 years and 20 years for coniferous and deciduous stands as indicators of full hydrologic recovery are based on stand leaf area (i.e. LAI - leaf area index). As LAI increases with growth of forest regeneration so does evapotranspiration and interception leading to a decrease in the volume of extra water generated by forest cover removal. Hydrologic recovery is assumed to be complete at the time of peak LAI for a stand.

1. Research by Loeffers *et al* (2002) in Alberta shows the time to maximum leaf area (LAI) for aspen dominated mixedwood stands varies from 15-25 years for fair to good sites.
2. Recent work by Brabender (2005) shows maximum LAI for lodgepole pine occurs somewhere between 27-35 years.
3. Further work is needed to characterize these relationships for white spruce and black spruce. Given their growth habitats time to maximum leaf area will be greater than that for aspen and pine.
4. Peak LAI for white spruce and black spruce may occur at of 40-50 years and 60-80 years may apply to white spruce and black spruce. These estimates are based on a strong relationship between volume growth and LAI (Brabender 2005).

In Step 3 an increase in simulated annual water yield  $\geq 20\%$  is used as a trigger to either modify existing harvest plans or to conduct further analyses. The selection of 20% as a limit was based on an analysis of the natural variability of annual water yield and peak flows (Watertight Solutions, 2005), a regression of simulated increases in annual water yield on percent area of watershed harvested and results from experimental watershed studies.

## **Natural Variability**

1. The analysis of natural variability of flows was done for the Grande Cache-Grande Prairie region. Flow data for 18 watersheds, with a length of record  $\geq 10$  years, in and adjacent to Weyerhaeuser Canada's FMA were used in the analysis. Natural variability for each watershed was defined as the average annual water yield  $\pm 2$  standard deviations.  $\{\%NV = ((2 \times \text{std}/0) \times 100)\}$ . This statistical approach was adopted as there are no standards or guidelines regulating the effects of forest harvesting on water flows and definitive data linking changes in flow to aquatic habitat do not exist.
2. Natural variability with respect to increases in annual water yield was defined as  $(0 + 2 \text{ std})$ . This definition includes the full range of variation above the mean flow associated with extreme hydrologic events and natural disturbances such as fire, insect and disease infestations.
3. Natural variability for the 18 watersheds averaged  $\sim 100\%$  (27%-145%) (Table 1), which greatly exceeds the potential effects of forest harvesting on water yield. Documented increased water yields following logging in Alberta range from 6% to 27% (Swanson and Hillman 1977; Swanson *et al* 1986).
4. The limits of natural variability for the 18 watersheds were used as a starting point to identify possible limits on increases in water yield. The values for full natural variability for each watershed were systematically reduced into multiples of  $(0 + 1 \text{ std})$ ,  $(0 + 0.5 \text{ std})$ ,  $(0 + 0.33 \text{ std})$ , and  $(0 + 0.25 \text{ std})$ . The maximum water yields identified by these reduced limits were then determined and described by their recurrence intervals<sup>1</sup> to identify "acceptable" increases in water yield (Table 1).
5. Recurrence intervals were used to identify "acceptable" increases by magnitude and frequency of occurrence. The effects of forest harvesting on water yield and peak flows are more pronounced for hydrologic events with recurrence intervals of 2-10 years. The effects of forest harvesting on more extreme events ( $> 10$  years) are usually small to nil (i.e. undetectable).
6. Average percent increases for the 18 watersheds were 47% for  $0+1 \text{ std}$ , 23.6% for  $0+0.5 \text{ std}$ , 15.6% for  $0+0.33 \text{ std}$  and 11.80% for  $0+0.25 \text{ std}$  (Table 1). Recurrence for the same categories were 6.7 years, 4.2 years, 3.7 and 3.4 years respectively. The three lower categories are considered most "acceptable" at they target water yields with recurrence intervals of 3-4 years.

## **Regression Analysis**

---

<sup>1</sup> Recurrence interval or return period expresses the average frequency that an event of given size can be expected to occur. For example, the 2-year peak flow on average will occur once every two years. Another way of expressing this is that in any given year the 2-year peak flow has a 50% chance of occurring. In contrast the 25 year peak flow has a 4% chance of occurrence in any given year. On a longer time frame the 2 year event can be expected to occur 50 times in 100 years and the 25 year event only 4 times in 100 years.

An alternative approach to identifying “acceptable” increase in annual water yield was a regression analysis of simulated water yield increases on percent area harvested in a watershed. The simulated water yields were obtained from a history of simulations done for forestry companies by Watertight Solutions Ltd. using WrnsAB2K.

1. The watersheds used in the analysis range in size from very small to large and cover a range of different forest cover types in Alberta (boreal and foothills).
2. Harvesting in most of the simulation runs was less than 40% of watershed area, with water yield increases averaging 6% with minimum and maximum values of 1.4% and 12%.
3. The regression curve indicates that harvesting 60%-80% of a watershed could increase maximum annual water yield by 15%-20%. These values should be viewed with some caution as the number of data are less for this part of the curve and the data points were for long term simulations where harvesting was frequent and affected 70-90% of watershed area.
4. Another point to acknowledge is that the regression analysis includes only maximum annual increases in water yield, which does not fully reflect the effects of snow redistribution and the potential for snow scour (i.e. sublimation) on harvest blocks. The inclusion of these effects could increase water yield responses.

**Table 1 Natural variability and possible percent increases in annual water yield based on multiples of natural variability (0+2 std) and average recurrence interval for each category (source "Variability of Precipitation and Streamflow, Grande Cache-Grande Prairie and Discussion of Guidelines for Water Yield and Peak Flow Increases, Prepared for Weyerhaeuser Canada Ltd., Grande Prairie by Watertight Solutions Ltd. March 2005).**

**Figure 1** Regression of simulated maximum annual increases in water yield on percent area of watershed harvested. Simulated increases were obtained from a series of simulations done in Alberta for watersheds varying in size from small to large (1 – 350 km<sup>2</sup>). The analysis indicates that harvesting 60%-80% of a watershed could increase maximum annual water yield by 15%-20%.

### Experimental Watershed Studies

The results from experimental watershed studies report increases in annual water yield ranging from 0% to 66%. The wide range in these results is a reflection of differences in climate (precipitation and energy), forest cover types, soils (i.e. soil water storage) and treatments. These studies are usually conducted on very small watersheds (2.5-7.5 km<sup>2</sup>) with treatments that in most cases removed 100% of the forest cover in a short period of time (1 season). The intent of many of these studies was to confirm the effects of forest cover removal and were done to seek the maximum effect.

Direct extrapolation of these results to forest harvesting operations must be done with care. Harvesting planning is usually done at a larger scale (3<sup>rd</sup>-4<sup>th</sup> order watersheds) and seldom if ever will a watershed be fully harvested in 1-2 seasons. There are only a few watershed studies where different levels of forest cover removal and long term post harvest evaluations (i.e. cumulative effects) are evaluated.

### Conclusions

In conclusion the protocol proposed by Weyerhaeuser Canada should be an effective method for screening harvest plans for 3<sup>rd</sup>-4<sup>th</sup> order watersheds to prevent water yield increases above "acceptable" levels. Using 40% of watershed area with coniferous and deciduous stands of ages ≤ 35 and 20 years in age to trigger an ECA-Alberta analysis should be effective in detecting and preventing water yield increases greater than 20%. The regression analysis shown in Figure 1 indicates that most water yield responses at ≤ 40% harvest level will be less than 12%.

The study of water flows in the Grande Cache-Grande Prairie area show annual water yield increases of 15%-20% fall within the range of natural variability and target annual water yields with recurrence intervals of 3-4 years, which are slightly above “average” conditions represented by the 2-year flows.

Improvements to this protocol and those of other companies undoubtedly will occur as better information and understanding of the hydrology of forested watersheds and hydrologic recovery become available. In particular, the development of “acceptable” flow increases for forest regions within the province (e.g. foothills versus boreal), better leaf area data for white and black spruce cover types, and flow data for headwater 3<sup>rd</sup> and 4<sup>th</sup> order watersheds.
